Dwarf Novae (DNe) are a subclass of cataclysmic variable stars, which are close binary systems in which matter transferred from a Roche-lobe filling secondary star is accreted by a primary white dwarf (Warner, 1995). In dwarf novae accretion proceeds through a disk which is the site of more or less regular outbursts. The recurrence time of these 2-6 mag outbursts can range from 10 days to several years. Dwarf novae can be divided into three subclasses: U Gem-type stars which have the most regular outburst cycles, SU UMa-type stars showing both short and very long outbursts (super-outbursts), and Z Cam stars. The last group is characterized by a “standstill” phenomenon: the decline from the outburst maximum is interrupted and the luminosity of the system settles to a value of ~ 0.7 mag lower than the peak luminosity. Such standstill may last from ten days to years and, after that phase, the system luminosity declines to the usual quiescent state.

In this brief paper we present B, V, R_c , I_c photometric observations of a sample of dwarf novae made in the years 1998-2002. We are mainly interested to obtain multi-color data of a large sample of DNe during all the outburst-cycle, a work that requires large availability of well-equipped small telescopes and generally good weather conditions for many days. Here we present the sporadic observations that do not cover the outbursts cycle because were obtained during the stand-still, or interrupted for persisting bad weather conditions. However, these informations are useful for a historical database of this class of sources, and because for many of them there are no optical color indices reported in the literature.

The photometric data were mainly obtained with the 0.72 m telescope of the Teramo Astronomical Observatory, and the 0.40 m Automatic Imaging Telescope of the Perugia University Observatory (Tosti et al., 1996). The instruments used and the photometric techniques have already been described in Spogli et al. (1998, 2000). We have also used the 0.24 m Schmidt-Cassegrain f/6.3 telescope equipped with an HISIS 23 CCD camera (Kodak 401-E, 768×512 pixels), and the 0.33 m Newtonian f/4.5 telescope equipped with an MX-916 CCD camera (768×512 pixels), of the “Subasio” astronomical station. Both the telescopes are endowed with a standard R_c Cousins broad-band filter. A comparison with results obtained with the other telescopes shows no relevant systematic difference within the typical standard deviation of each instrument. The data reported in Table 1 are obtained in differential photometry using the calibration stars reported in Misselt

(1996). Moreover, we calibrated these comparison stars with the I_c filter by observing, on photometric nights, several standard stars (Landolt, 1992) having $(B - V)$ from -0.2 to 1.4 , over a wide range of airmass.

The selected dwarf novae have been observed in different phases of luminosity: a few of them were in outburst, others at minimum or in stand-still. For the dwarf novae that were in outburst at the time of the observations, we calculated the spectral index α (Table 2) using the same procedure described in Spogli et al. (1998) and neglecting interstellar reddening.
